Abstract. A latitudinal cross-section and vertical profiles of iodine monoxide (IO) are reported from the marine boundary layer of the Western Pacific. The measurements were taken using Multi-Axis Differential Optical Absorption Spectroscopy (MAX-DOAS) during the TransBrom cruise of the German research vessel *Sonne*, which led from Tomakomai, Japan (42° N, 141° E) through the Western Pacific to Townsville, Australia (19° S, 146° E) in October 2009. In the marine boundary layer within the tropics (between 20° N and 5° S), IO mixing ratios ranged between 1 and 2.2 ppt, whereas in the subtropics and at mid-latitudes typical IO mixing ratios were around 1 ppt in the daytime. The profile retrieval reveals that the bulk of the IO was located in the lower part of the marine boundary layer. Photochemical simulations indicate that the organic iodine precursors observed during the cruise (CH₃I, CH₂I₂, CH₂ClI, CH₂BrI) are not sufficient to explain the measured IO mixing ratios. Reasonable agreement between measured and modelled IO can only be achieved if an additional sea-air flux of inorganic iodine (e.g., I₂) is assumed in the model. Our observations add further evidence to previous studies that reactive iodine is an important oxidant in the marine boundary layer.

1 Introduction

Past studies indicated that inorganic iodine may exert considerable influence on the oxidation capacity and particle formation of the marine atmosphere (e.g., Chameides and Davis, 1980; Solomon et al., 1994; Platt and Hönninger, 2003; Saiz-Lopez et al., 2012). Unequivocal evidence for the presence

of reactive iodine species and the important role they play in various atmospheric processes have been provided through a suite of ground, ship and satellite-based observations of reactive iodine species (I₂, IO and OIO) (e.g. Read et al., 2008; Schönhardt et al., 2008; Seitz et al., 2010; Mahajan et al., 2010b) as well as of iodine tied to aerosols (e.g. Burkholder et al., 2004; Hayase et al., 2010; McFiggans et al., 2010) along with supporting modelling studies (e.g., von Glasow et al., 2002; Saiz-Lopez et al., 2006, 2012; Sommariva et al., 2012, and references therein).

Past observational studies on atmospheric iodine already covered many areas of the globe, including both polar regions, coastal regions, islands at mid- and low-latitudes and salt lakes (e.g. Saiz-Lopez et al., 2012, and references therein).

Nevertheless, information regarding reactive iodine in the air over the open ocean remained sparse mainly due to a lack of shipborne observations. Table 1 provides an overview of the recent ground-based observations of IO in the troposphere over open ocean, using the DOAS technique. Land-based IO measurements with a strong connection to the ocean have been conducted on several islands. For example at Tenerife, IO mixing ratios up to 3 ppt were observed (Allan et al., 2000), or on the Maldives IO mixing ratios ranging between 2.4 and 3.1 ppt were inferred for assumed boundary layer heights of 1 km and 350 m, respectively (Oetjen, 2009). In addition, on the Cape Verde Islands IO mixing ratios ranging between 1 and 3 ppt were observed with a solar radiation driven diurnal cycle (Read et al., 2008; Mahajan et al., 2010a). Furthermore, in a recent study a latitudinal cross-section of IO was inferred by Mahajan et al. (2012)

Table 1. Past open ocean ground-based observations of IO in the troposphere using the active and passive DOAS technique.

Region	Location	Instrument	Max. Ratio [ppt]	Mix. Error $\pm(2\sigma)$ [ppt]	Reference
land-based	Tenerife, Spain (1997)	LP-DOAS	3	0.3	Allan et al. (2000)
	Tenerife, Spain, free troposphere (2010)	MAX-DOAS	0.4	0.2	Puente-dura et al. (2012)
	Cape Verde (2006–2007)	LP-DOAS	3.1	0.4	Mahajan et al. (2010a)

with maximum IO mixing ratios reaching 1.2 ppt in regions of low biological activity, i.e., in the latitude bands 5° N to 20° N and 20° S to 40° S at around 80° W to 130° W in the Eastern Pacific.

Using the SCIAMACHY satellite instrument, IO was also detected from space, mostly over high southern latitudes and over some biological hot-spot regions (e.g., the African and South American west coasts), where upwelling of nutrient rich waters and tentatively large emissions of iodocarbons occur (Saiz-Lopez et al., 2007; Schönhardt et al., 2008, 2012). However, satellite-based IO remote sensing is limited by the relatively low detection sensitivity, in particular, over surfaces with low reflectivity, such as the tropical oceans, where the presence of IO can be suspected. Therefore, more IO measurements covering wider and yet unexplored oceans, such as the Pacific, are highly desirable, in order to determine the importance of reactive iodine for the photochemistry and its potential for aerosol formation in the marine boundary layer (MBL) on a global scale.

Information regarding the vertical distribution of IO is also sparse; the only published IO vertical profiles were inferred from MAX-DOAS measurements at Izaña, Canary Islands (Puente-dura et al., 2012). In fact, these measurements not only revealed the presence of sizable amounts of IO within the marine boundary layer, but also indicated small amounts in the overlaying free troposphere.

The present paper reports on shipborne MAX-DOAS measurements in the Western Pacific from which a latitudinal cross-section and vertical profiles of IO are inferred. These IO measurements are complemented by sea-to-air flux measurements of the organic iodine precursor gases methyl iodide (CH₃I), chloriodomethane (CH₂ClI), bromiodomethane (CH₂BrI) and diiodomethane (CH₂I₂) and the results of a photochemical model which aim to close the budget of organic and inorganic iodine source strengths, the atmospheric IO abundance and the strength of potential sink processes. It is argued that by adjusting the source strength of the iodocarbons and inorganic iodine, the marine surface

air may sustain the detected abundance and vertical profile of IO.

The paper is organised as follows: Sect. 2 gives an overview of the TransBrom *Sonne* cruise in the Western Pacific. In Sect. 3, the major tools and methods of the study are described. Section 4 reports on the results with respect to the observed and inferred source strengths of organic iodine precursors, the photochemistry of inorganic iodine and possible correlations with observed IO. Section 5 compares the measurements to model calculations and Sect. 6 concludes the study.

2 The TransBrom *Sonne* cruise during October 2009

The TransBrom expedition was conducted aboard the German research vessel (R/V) *Sonne* departing in Tomakomai, Japan (42° N, 141° E) on 9 October 2009 and arriving at Townsville, Australia (19° S, 146° E) on 24 October 2009 (cruise length of 7500 km). An overview of the meteorology during the cruise is given by Krüger and Quack (2012). Here the viewing conditions are added. At the beginning of the cruise, the weather was influenced by the typhoon *Melor* which had weakened to an extratropical storm when reaching the R/V *Sonne* causing heavy rain and strong winds in the harbour of Tomakomai on 9 October 2009. On 10 October 2009, the weather was characterised by almost clear skies providing a good visibility, but on 11 and 12 October 2009 the cloud coverage increased. During the night of 13 October 2009, the next tropical depression (*Nepartak*) hit the R/V *Sonne* causing the largest winds recorded during the whole cruise and heavy rain until noon. On 14 October 2009 clear skies provided the best viewing condition during the whole cruise. In the afternoon of 15 October 2009, the R/V *Sonne* encountered again high wind speeds due to the tropical depression *Lupit* passing by. The days from 15 to 22 October 2009 were partly cloudy, and atmospheric instability initiated large convective cells which on occasions led to precipitation

during the afternoons. The weather on the final days of the cruise was again rather sunny with infrequent occurrence of clouds.

In order to facilitate the discussion later in the paper, the whole cruise track is divided into three parts, part 1 ranging from Tomakomai, Japan (42° N, 141° E) to (20° N, 146° W) (9–14 October 2009), part 2 from (20° N, 146° W) to (8° S, 154° W) (14–21 October 2009) and part 3 part from (8° S, 154° W) to Townsville (19° S, 146° E) (21–24 October 2009).

Major objectives of the TransBrom *Sonne* cruise were the investigation of the halocarbon concentrations in the surface seawater and air, and the estimation of their sea-air source strengths and sinks. This appears to be relevant since the Western Pacific is regarded as the main “entrance gate” for naturally emitted halocarbons entering the stratosphere (Bonazzola and Haynes, 2004; Krüger et al., 2008; Fueglistaler et al., 2009). Further, Fourier Transform infrared spectrometry (FTIR) measurements of CO and O₃ (Ridder et al., 2012) as well as satellite and in-situ measurements of phytoplankton complemented our measurements. Finally, our trace gas studies were complemented by meteorological measurements and the release of radio- and ozonesondes (Krüger and Quack, 2012).

Two MAX-DOAS instruments were operated next to each other aboard the R/V *Sonne* with the same line-of-sight. The IUP Bremen group focussed on the measurements of NO₂ and HCHO and their validation with satellite measurements (Peters et al., 2012) and the IUP Heidelberg group focussed on the retrieval of IO mixing ratios and profiles in the MBL along the cruise track (this study).

3 Methods

While IO was measured using the MAX-DOAS method, air samples were taken simultaneously, although at a lower frequency, for the analysis of some major iodocarbon species (CH₃I, CH₂I₂, CH₂CI, CH₂BrI) from which sea-air fluxes were inferred. Since the measured IO mixing ratios were also compared to simulations of the one-dimensional photochemical model MISTRA v7.4.1 (von Glasow et al., 2002; Sommariva et al., 2012), some details of the MISTRA simulations are provided below.

3.1 The (MAX-)DOAS measurement principle

For the retrieval of IO, the method of Differential Optical Absorption Spectroscopy (DOAS) was applied (Platt and Stutz, 2008). This method is a remote sensing technique using scattered sunlight that is attenuated along its light path in the atmosphere according to the Lambert-Beer law. It relies on the fact that the optical density can be separated in a narrow (differential) band component accounting for the absorption

processes of the different trace gas molecules and a broad band component describing the scattering effects.

In the Multi-Axis DOAS (MAX-DOAS) technique (Hönninger et al., 2004; Wittrock et al., 2004), spectra of scattered sunlight are recorded under different elevation angles α between the zenith and the horizon. Low elevation angle measurements have a higher sensitivity to lower tropospheric layers and, thus, the MAX-DOAS method has an increased sensitivity towards tropospheric absorbers located near the surface.

The MAX-DOAS measurements yield differential slant column densities (dSCDs) ΔS for each fitted trace gas: $\Delta S(\alpha) = S(\alpha) - S_{\text{ref}}$ with $S(\alpha)$ being the slant column density (SCD) recorded at the elevation angle α and S_{ref} being the SCD of the Fraunhofer reference spectrum usually measured towards the zenith ($\alpha = 90^\circ$). The SCD is defined as the concentration c of a specific absorber integrated along the light path L and is given in units of molec cm⁻².

Using radiative transport models, the SCDs can be converted to vertical column densities (VCD) V by simulating the air mass factor (AMF) A , which is the ratio of S and V . V is defined as the concentration c integrated along the vertical height z and is in turn independent of the length L of the light path.

3.2 The MAX-DOAS instrument

The IUP Heidelberg MAX-DOAS instrument on the R/V *Sonne* consisted of the following major parts: a telescope unit, in which a plano-convex quartz lens collected the skylight into the approximately circular entrance area of a quartz fibre bundle with 37 individual optical fibres of 100 μ m core diameter forming a telescope field of view of 0.5°. At the fibre bundle exit, the single optical fibres of the bundle were arranged to a single column serving as the entrance slit of the Acton SpectraPro 300i Czerny-Turner optical spectrometer. The optical spectrometer was equipped with an Andor CCD detector camera (model DU 440-BU) with 2048 horizontal (i.e., in dispersion direction) and 512 vertical pixels. The optical spectrometer covered a wavelength range from 327 nm to 470 nm, with a full width half maximum resolution of 0.5 nm, or 7.2 detector pixels. A personal computer was used to control the instrument, to store the data and for online data analysis. The performance of the instrument was assessed during a recent intercomparison campaign (Roscoe et al., 2010).

The telescope was attached at the portside on top of the rail of the upper deck of the R/V *Sonne*, approximately 15 m above sea level. The viewing direction was oriented perpendicular to the heading of the ship. The rolling movement of the ship (rotation of the ship along the heading axis) was largely compensated for by employing an inclinometer, of which the output signal was used to continuously stabilise the elevation angle of the telescope during the measurements. The optical spectrometer was placed in the scientific bridge

room of the R/V *Sonne* and kept at a temperature of 38 °C, in order to guarantee a stable optical imaging.

During the routine measurement mode, a set of 1000 scattered skylight spectra was added for each chosen elevation angle, $\alpha = 90^\circ$ (zenith), 20° , 10° , 7° , 5° , 3° , -45° . One elevation angle sequence lasted for about seven minutes and the sequences were continuously repeated as long as the solar zenith angle (SZA) was lower than 85° . During twilight ($85^\circ < \text{SZA} < 97^\circ$), only zenith measurements were performed, followed by detector dark current and offset measurements during nighttime.

3.3 DOAS data analysis

The scattered sunlight spectra measured by MAX-DOAS were analysed for the absorption of IO and O₄ using the software *WinDOAS* provided by the IASB/BIRA (Belgian Institute for Space Aeronomy) (Van Roozendaal and Fayt, 2001). The *WinDOAS* code was also used for the convolution of all absorption cross-sections reported in the literature, whereas the Ring spectrum was calculated using the software *DOASIS* (Kraus, 2006). In *DOASIS* the Ring spectrum was calculated according to Bussemer (1993) by dividing a Raman smoothed skylight spectrum with the original skylight spectrum (i.e., the Fraunhofer reference spectrum), both being wavelength normalised.

Since in the tropics at local noon, the measured zenith sky spectra were too bright leading to a saturation of the detector, instead local noon skylight spectra measured at an elevation angle of $\alpha = 20^\circ$ were taken as Fraunhofer reference spectra.

Since during an individual elevation sequence the changes of the stratospheric slant column densities were small due to similar light paths in the stratosphere for all elevation angles, their contribution cancelled out for two adjacent $\alpha = 20^\circ$ measurements and, thus, $\Delta S(\alpha)$ did not contain any stratospheric residual absorption. For the spectral retrieval, each 20° elevation angle spectrum was allowed to be wavelength-shifted relative to the high resolution solar Fraunhofer spectrum of Kurucz et al. (1984). Thereby, changes in the wavelength calibration, for example, due to variations of the spectrometer temperature, were compensated for. For every 20° Fraunhofer reference spectrum, a Ring spectrum was calculated and shifted the same way as the reference spectrum. The respective reference and Ring spectrum were then used to evaluate the measured skylight spectra recorded at the other elevation angles of the measurement sequence.

The IO analysis was performed in the wavelength interval ranging from 417.5 to 438.2 nm, encompassing three vibrational IO absorption bands. The following absorption cross-sections were included into the spectral retrieval: an IO spectrum from Spietz et al. (2005), an NO₂ spectrum at 298 K from Vandaele et al. (1998), an O₃ spectrum at 223 K from Bogumil et al. (2000), an H₂O spectrum from Rothman et al. (2009) (HITRAN), and finally an atmospheric Ring spectrum calculated according to recommendations of Chance

and Spurr (1997). The latter accounted for the filling-in of the solar Fraunhofer lines by rotational Raman scattering of air molecules. An absorption spectrum of glyoxal (Volkamer et al., 2005) was not included in the spectral retrieval, as glyoxal was not found in a spectral pre-analysis performed in the wavelength range from 450 to 461 nm, encompassing the largest glyoxal absorption band. Furthermore, a multiplicative polynomial of 3rd order was included in order to account for the broadband spectral structures due to atmospheric Rayleigh and Mie scattering. Spectrometer straylight was accounted for by an additive polynomial of first order (i.e., assuming a linear wavelength dependence of the straylight). The whole package of reference spectra was allowed to be wavelength-shifted relative to the ratio of measured atmospheric spectra. All absorption cross-sections were convolved to the spectral resolution of the instrument using the mercury emission line located at 404.66 nm.

In addition, spectral retrieval exercises indicated that inelastic Vibrational Raman Scattering (VRS) by oceanic water also needed to be considered. The VRS is known to be in particular relevant for measurements over oceanic water of low chlorophyll concentrations (Vountas et al., 2003; Dinter, 2005). Hence a VRS compensation spectrum (provided by T. Dinter, IUP Bremen, personal communication, 2011) was included in the spectral retrieval. A typical example for the retrieved IO absorption including the oceanic VRS is shown in Fig. 1a. The spectrum was recorded at 19.87° N and 147.15° E at an elevation angle of 3° at 15:13 local time ($\text{SZA} = 55.79^\circ$) on 14 October 2009. Spectral retrieval exercises including/excluding the VRS indicated that the inferred IO dSCD was $1.56 \times 10^{13} \text{ molec cm}^{-2}$ versus $1.89 \times 10^{13} \text{ molec cm}^{-2}$ and the residual root-mean-square (RMS) was 1.50×10^{-4} versus 1.67×10^{-4} , respectively, i.e., the IO dSCD increased by about 20 % while the residual increased by about 10 %, thus, providing evidence that the VRS compensation spectrum needed to be included in the spectral retrieval. Furthermore, modelling studies of the relative number of photons that are back-scattered from the ocean surface layer using the radiative transfer model McArtim (see Sect. 3.4.1) suggested that, for elevation angles smaller than 10° , a wavelength of 428 nm, an SZA of 30° , a relative azimuth angle of 90° and an oceanic albedo of 0.054 (Jin et al., 2002), 10–15 % of the detected photons were back-scattered in the oceanic surface layer. Both findings led us to include a VRS compensation spectrum in the spectral retrieval.

The analysis of O₄ was performed in the wavelength interval ranging from 348 to 369 nm, where a single absorption band is located. The following absorption cross-sections were included into the spectral retrieval: O₄ from Hermans et al. (1999), BrO at 298 K from Wilmouth et al. (1999), HCHO from Meller and Moortgat (2000), NO₂ at 298 K, O₃ at 223 K and 243 K (for the references see above) as well as a Ring spectrum. For the multiplicative and additive polynomials, the same degrees were used as for the IO spectral retrieval.

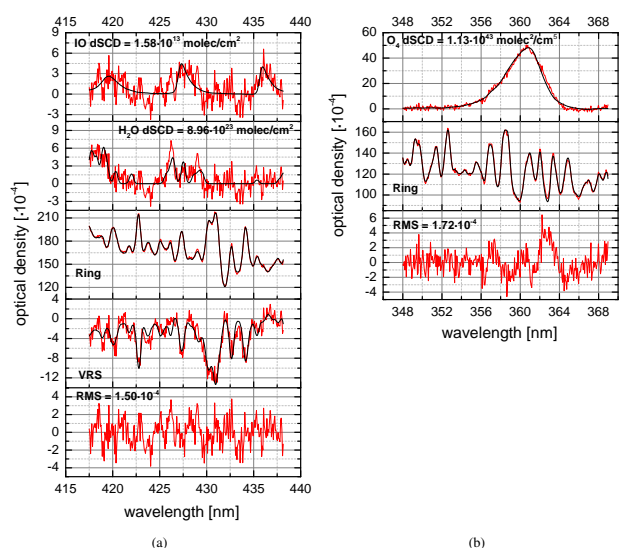

Fig. 1. Example for a spectral retrieval of (a) IO including a VRS compensation spectrum and (b) O₄. The spectrum was recorded at an elevation angle of 3°, an SZA of 55.79°, at 19.87° N and 147.15° W and 15:13 local time (UTC + 10h) on 14 October 2009. The black lines indicate the fitted absorption cross-sections, whereas the red lines indicate the retrieved spectral signatures. The retrieved absorption structures of NO₂, O₃, HCHO, and BrO are not shown.

Figure 1b shows an example for an O₄ spectral retrieval. In this case, the retrieved O₄ dSCD was 1.13×10^{43} molec²cm⁻⁵ with the RMS of the residual spectrum amounting to 1.72×10^{-4} .

For the further analysis, only data points with an RMS smaller than 4×10^{-4} were used.

3.4 Retrieval of aerosol and trace gas vertical profiles from MAX-DOAS measurements

Vertical profiles of the aerosol extinction and IO mixing ratios were derived using the well-established method of optimal estimation (Rodgers, 2000). The aerosol and trace gas retrieval algorithm, as previously described by Frieß et al. (2006) and Frieß et al. (2011), was used and adapted for this study. Briefly, the optimal estimation method compared measured O₄ and IO dSCDs with model simulations from radiative transfer modelling, using a priori vertical profiles as an additional constraint. The resulting maximum a posteriori (MAP) solutions yielded the aerosol extinction and IO mixing ratio profiles, respectively.

The following radiative transfer model parameters were chosen for both, the aerosol and the IO retrievals: pressure, temperature and humidity were adapted from the US standard atmosphere, and the surface albedo was set to 6 %. Profile information was retrieved for time intervals of 15 min for

individual layers, each 100 m in vertical extent, ranging from the surface up to 2000 m altitude.

3.4.1 Details of the vertical profile retrieval

In a first step, aerosol profiles were retrieved using a retrieval algorithm based on the SCIATRAN radiative transfer model (Rozanov et al., 2005). Since the length of the light paths and, thus, the O₄ dSCDs observed at different elevation angles depend on the atmospheric aerosol loading, information on the aerosol extinction profile can be derived on the basis of the observed O₄ dSCDs (Wagner et al., 2004; Sinreich et al., 2005; Frieß et al., 2006). As a priori, an aerosol extinction profile with a surface extinction of 0.14 km^{-1} and linearly decreasing to zero at an altitude of 2 km was chosen. The a priori error was set to 100 %. For aerosol scattering, an aerosol single scattering albedo of 0.95 and a Henyey-Greenstein phase function with an asymmetry parameter of 0.72 were assumed. O₄ dSCDs inferred from different elevation angles from the 360.8 nm band served as measurement vector. According to findings by Cl  mer et al. (2010), the absorption cross-section of O₄ was previously underestimated by as much as 25 % and, hence, the O₄ cross-section from Hermans et al. (1999) is multiplied by 1.25.

IO vertical profiles were derived using our trace gas retrieval algorithm, which employed the McArtim Monte Carlo radiative transfer code as a forward model (Deutschmann et al., 2011). The retrieved extinction profiles from above served as input parameter for modelling the radiative transfer. The a priori IO profile was assumed to exponentially decrease with altitude, with a scale height of 1 km and a surface volume mixing ratio (VMR) of 2 ppt. The a priori error was set to 100 % and the same 100 m layers as in the case of the aerosol retrieval were used. The profiles were simulated with 10^4 photon trajectories.

For the measurements under clear skies on 14 October 2009, a comparison between measured and modelled O₄ and IO dSCDs is shown in Fig. 2. A good agreement between modelled and measured dSCDs was achieved, showing that the radiative transfer model was able to reproduce the measurements with the chosen assumptions. Figure 3 shows average aerosol and IO averaging kernels. The aerosol and IO retrievals showed a distinctively different behaviour, with the aerosol retrieval being only sensitive to the lowermost ≈ 500 m of the atmosphere (note that the sensitivity varies with aerosol content due to the non-linear nature of the inverse problem). During the whole cruise the degrees of freedom for signal (DFS) of the aerosol retrieval ranged between 0.78 and 1.29 with an average value of 1.15. Somewhat better sensitivity was achieved for the IO retrieval, where the averaging kernel indicated that information on the vertical profile was retrieved for the lowermost 1000 m, and the DFS ranged between 1.30 and 2.26 with an average value of 1.97.

Fig. 2. Measured (squares) and simulated (crosses) O_4 dSCDs (top) and IO dSCDs (bottom) for 14 October 2009. The colour coding indicates the elevation angles.

Figure 4 shows a comparison between the aerosol optical depth (AOD) retrieved from MAX-DOAS measurements and from data of a hand-held Sun photometer. Sun photometer data during the TransBrom *Sonne* cruise was very sparse and data was only available for several hours on six days. During these occasions, the AODs inferred from the MAX-DOAS and Sun photometer measurements showed good agreement except for 17 October 2009, when the AODs inferred from the Sun photometer observation were significantly lower than inferred from MAX-DOAS measurements.

3.4.2 Error characterisation and information content

Several sources contributed to the overall error of the retrieved profile. First, random and systematic errors (called noise error) of the trace gas spectral analysis propagated into the profile retrieval. Second, the limited information content of the measurements resulted in a limited height resolution as quantified by the averaging kernels, yielding the so-called smoothing error. Third, the uncertainty in the forward radiative model parameters caused a systematic error component. Furthermore, the choice of the a priori constraint affected the results of the retrieval. Since a detailed error analysis of the aerosol retrieval was already provided by Frieß et al. (2006), the focus of the following error discussion was put on the IO vertical profile retrieval.

The errors of the IO spectral analysis (noise error) were given by the IO fit error and the systematic errors. For example, for the measurement on 14 October 2009, the average (and typical) IO fit error was about $1.6 \times 10^{12} \text{ molec cm}^{-2}$ ($\approx 10\%$ of the average IO dSCD) for an observation at an elevation angle of 3° .

In order to test the sensitivity of the spectral retrieval and of the forward model parameters on the profile retrieval, retrievals were performed for different sets of parameters. Table 4 specifies the different parameters and the corresponding inferred IO dSCDs, VMRs and VCDs and the respective

Fig. 3. Averaging kernels for inferred AOD and IO, both averaged for the data from all profile retrievals.

Fig. 4. Comparison of the aerosol optical depth (AOD) at 360 nm retrieved from MAX-DOAS (black squares) and from Sun photometer (red circles) measurements. The Sun photometer data were converted from AODs measurements at 440 nm to AODs at 360 nm, using the Ångström exponents derived from the Sun photometer measurements.

absolute IO retrieval errors, averaged over many profile retrievals for a single day (14 October 2009). Systematic errors arose e.g., from excluding or including different absorption cross-sections in the DOAS fitting procedure. The following parameters were varied: (a) An H_2O absorption cross-section from HITRAN 2009 instead of HITRAN 2006 was included. Here it was found that the HITRAN 2009 H_2O yielded approximately 21 % lower IO dSCDs and 12 % lower dSCDs errors, most likely due to a wavelength shift of the HITRAN 2006 versus HITRAN 2009 H_2O absorption cross-section. (b) Inclusion of a glyoxal absorption cross-section in the spectral retrieval resulted in lower IO dSCDs ($\approx 19\%$), but much higher dSCD errors ($\approx 38\%$). (c) Inclusion or omission of a VRS compensation spectrum led to the results already stated above i.e., excluding the VRS compensation spectrum resulted in approximately 16 % larger IO dSCDs and 25 % larger dSCD errors.

The average VMR noise error of the final IO profile retrieval amounted to 0.3 ppt, which corresponded to approximately 25 % of the average VMR of 1.3 ppt. However, here the smoothing error dominated the IO retrieval error and

resulted in an average mixing ratio error of 0.8 ppt. Accordingly, the average total VMR error was 0.9 ppt.

The main uncertainty of the forward model parameter error was due to uncertainties in the assumed aerosol extinction profile. For example, changing the assumed AOD by $\pm 20\%$, which was much larger than the typical total retrieval error of 5 %, modified the IO VMR by approximately $\pm 22\%$.

A further test consisted of using an exponentially decreasing IO a priori profile with a scale height of again 1 km and a surface VMR of 1 or 4 ppt instead of 2 ppt. It was found that changing the a priori profile shape had a large impact on the shape of the inferred profile, which was a result of the limited information content of the profile retrieval.

Another error potentially arose from the uncertainty of the viewing direction. Assuming that the inclinometer did not correctly compensate for the rolling movement of the ship, an elevation offset of 1° was implemented in the retrieval. Compared to the retrieval excluding an elevation offset the total VMR error was approximately 17 % larger and the inferred VMR increased by 22 %.

In summary, the systematic error determined using a Gaussian square sum of the individual error components, amounted to $\approx 0.95 \times 10^{12} \text{ molec cm}^{-2}$ (30 %) and 0.65 ppt (60 %) for the inferred IO VCD and VMR, respectively. The daily averaged DFS for 14 October 2009 was $d_s = 1.98$, but varied considerably with atmospheric visibility.

3.5 Iodocarbons measurements

Occasional air samples were collected using unpressurised canisters and analysed for major halocarbons using the GC/MS analytical system installed aboard. In addition, air samples were taken at higher frequency using pressurised canisters, which were analysed for halocarbons at the Rosenstiel School of Marine and Atmospheric Sciences (RSMAS) in Miami by the group of Elliot Atlas (Quack et al., 2013). Furthermore, a few air samples were analysed for some halocarbons at the Institute for Atmospheric and Environmental Sciences, University of Frankfurt, Germany by the group of Andreas Engel. All these samples, analysed at different laboratories, showed a good agreement for some brominated compounds (Brinckmann et al., 2012). The direct analysis of the samples analysed aboard the R/V *Sonne* with the GC/MS system was found to be necessary, since some iodinated halocarbons e.g., CH_3I , CH_2I_2 , CH_2CII and CH_2BrI , are known to be unstable in the air canisters upon storage. Calibration of the on-board measurements was performed using liquid standards, since gaseous standards were not available. Three stock solutions of chlorinated, brominated and iodinated compounds were prepared in pentane, and volumetrically diluted with methanol to environmental concentrations. Analysis of the liquid standards was performed through the same analytical set-up as for seawater and atmospheric samples analysed on-board. Intercalibration of the analytical systems was performed with a) a NOAA gas standard mixture

and b) with the CHBr_3 and CH_3I atmospheric data obtained by all three groups. The agreement between the two canister storage methods were generally better than 5 %, while the samples analysed with the on-board GC/MS system differed by as much as 20 % in absolute terms, but generally showed a good agreement in relative terms. The iodinated compounds CH_2I_2 , CH_2CII and CH_2BrI were only calibrated with the standard solutions resulting in an estimated uncertainty of 20 %.

3.6 Photochemical modelling

The IO measurements were compared to simulations of the marine iodine chemistry performed with the one-dimensional (1-D) photochemical model MISTRA v7.4.1 (von Glasow et al., 2002; Sommariva et al., 2012). MISTRA is a 1-D Lagrangian model which includes a detailed treatment of the dynamics and thermodynamics as well as a microphysical module that explicitly calculates particle growth and the interaction with radiation. MISTRA includes a detailed and recently updated gas and aqueous phase chemical mechanism, with a focus on halogen chemistry, as recently described in Sommariva and von Glasow (2012) and Sommariva et al. (2012).

The model was set up to simulate the transport of air masses in the MBL over the Pacific Ocean for a latitude of 10°N during October. The model meteorology was developed assuming a constant boundary layer height of 800 m, and a surface wind speed and temperature of 6 m s^{-1} and 295 K, respectively. These assumptions were based on the average meteorological observations made during the TransBrom cruise (Krüger and Quack, 2012), though sensitivity runs showed that the model results, with respect to iodine species, were not very sensitive to meteorological parameters under the conditions encountered during the TransBrom cruise.

Due to a lack of measurements during the campaign, the model was initialised based on previous measurements in a tropical remote region of the open ocean (Sommariva and von Glasow, 2012): $\text{NO}_x \approx 20 \text{ ppt}$, $\text{O}_3 \approx 30 \text{ ppb}$ and $\text{CO} \approx 130 \text{ ppb}$. The model was run for 1.5 days to spin-up the meteorology and the microphysics, then the chemistry was re-initialised and the model ran for another three days. The simulation represented a clean air mass that travelled for at least three days in the marine boundary layer of the tropical Western Pacific Ocean.

In model run 0 the only source of iodine was a mixture of iodinated hydrocarbons emitted from the ocean surface, according to the iodocarbon measurements. The flux of iodocarbons was calculated off-line, in order to reproduce the atmospheric observations of CH_3I , CH_2I_2 , CH_2CII , CH_2BrI , $\text{C}_2\text{H}_5\text{I}$, $\text{C}_3\text{H}_7\text{I}$ made during the TransBrom cruise (see Table 2). As CH_2CII was considerably elevated in cruise part 3, the dataset was split into two separate model runs representative for the tropical region of cruise part 2 and with elevated

Table 2. Iodocarbons measured during the TransBrom cruise. Since CH₂ClI mixing ratios varied during the cruise, average values for cruise part 2 and part 3 were calculated.

	CH ₃ I [ppt]	CH ₂ ClI cruise part 2 [ppt]	CH ₂ ClI cruise part 3 [ppt]	CH ₂ BrI [ppt]	CH ₂ I ₂ [ppt]
Lifetime	6 days ¹	0.1 days ²		≈ 1 h ³	2–10 min ³
Average	0.52	1.43	7.41	0.19	0.56 ¹
Minimum	0.11	0.31	0.51	0.14	0.09
Maximum	0.93	4.162	13.85	0.25	1.76

¹ Bell et al. (2002)² Rattigan et al. (1997)³ Mössinger et al. (1998)

CH₂ClI as during cruise part 3. Furthermore, two model runs with different levels of additional I₂ fluxes as listed in Table 3 were performed (run 1 and 2).

The inferred iodocarbon fluxes were also compared to iodocarbon fluxes used in previous model studies: the fluxes from (a) Vogt et al. (1999) and from (b) von Glasow et al. (2002) were very similar, although they differ by a factor of two for the flux of CH₂ClI and C₃H₇I (assumed as the sum of the two isomers). The flux of CH₂I₂ was assumed to be the same in both cases (Vogt et al. (1999) did not report a flux for this species). The ratios between the fluxes of the different species in both modelling studies were estimated based on the measurements of total organic iodine reported during field studies (Vogt et al. (1999) and references therein). A more recent study by Jones et al. (2010) reported observations of the sea-air fluxes of individual iodocarbons for (c) the open ocean region in the tropical and sub-tropical Atlantic Ocean and for (d) the Mauretanian upwelling region (high productivity region off the coast of West Africa). These fluxes were significantly different from previous estimates, particularly for the short-lived compounds such as CH₂I₂ and CH₂ClI, resulting in an overall weaker source of iodine in the remote ocean, even in high productivity regions (Table 3). The flux of CH₂ClI in the Atlantic Ocean reported by Jones et al. (2010) is even ten times lower than the flux calculated for part 3 of the TransBrom cruise in the Western Pacific.

4 Results and discussion

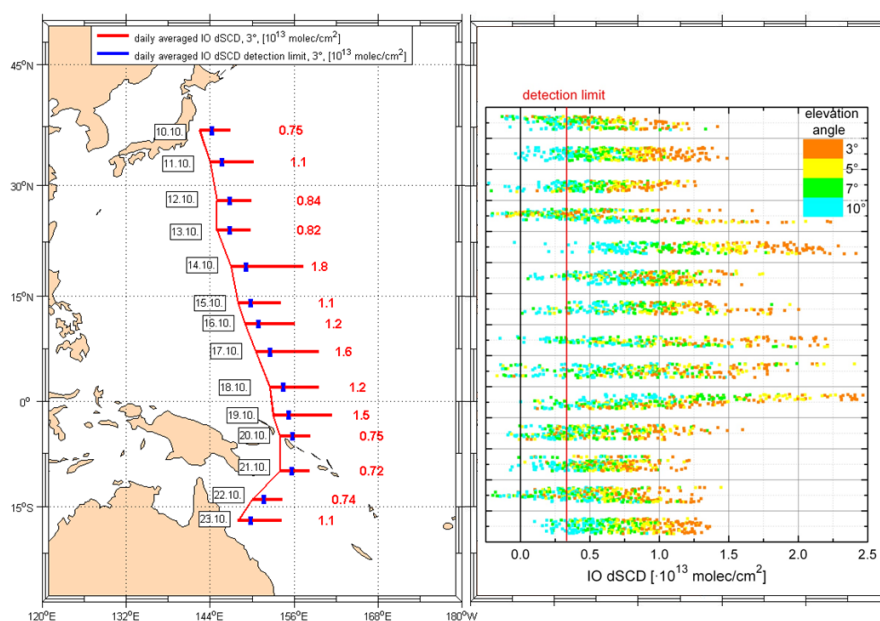

Figure 5 shows the IO dSCDs for an elevation angle of 3° together with the daily averaged IO dSCDs and the respective detection limits for the TransBrom cruise track. The average detection limit (assumed to be 2σ) was similar for all elevation angles and amounted to $S_{\min} = (3.32 \pm 0.72) \times 10^{12}$ molec cm⁻² for an elevation angle of 3°. As expected the IO dSCDs increased with decreasing elevation angle, indicating that IO was present close to the surface, except for periods of heavy rain e.g., in the morning of 13 October 2009 and in the afternoon of 18 October 2009 as well as around noon on 20

to 22 October 2009. During these periods, no clear separation of the measured IO dSCDs for different elevation angles was observed owing to the low visibility. For rainy periods, the inferred IO dSCDs were also lower than on clear days. Compared to the measurements in cruise part 1 and 3, in cruise part 2 the measured IO dSCDs were larger reaching typical IO dSCDs of $(1\text{--}1.8) \times 10^{13}$ molec cm⁻² and maximum IO dSCDs of 2.5×10^{13} molec cm⁻². The largest IO dSCDs were observed on cloud free sunny days e.g., on 14 October 2009, but unfortunately due to software problems the early morning data were missing. Moreover, on days with almost clear sky and little cloud coverage, the measured IO dSCDs did not show a distinct diurnal cycle for SZAs lower than 84°. Contrary to this finding, on overcast days e.g., on 19 October 2009, enhanced IO dSCDs were observed for morning as compared to evening measurements. The enhanced IO dSCDs as well as the O₄ dSCDs (not shown here) seen in the morning of 19 October are most likely caused by radiative transfer effects. On overcast days the length of the light path reaching the MAX-DOAS instrument changes a lot due to multiple scattering within clouds.

The inferred IO dSCDs were also compared to the measurements simultaneously taken with the Bremen instrument (for instrument description see Peters et al., 2012) for 14 October 2009 (Fig. 6). In order to avoid direct sunlight and detector saturation effects, the spectra from the IUP Bremen instrument were analysed against a single daily zenith Fraunhofer reference spectrum taken at an SZA of 45°, whereas for the IUP Heidelberg retrieval the 20°, spectrum taken during each elevation sequence was used as a Fraunhofer reference spectrum. For this comparison, however, the IO dSCDs from Heidelberg were also analysed against a single daily zenith Fraunhofer reference spectrum taken at an SZA of 45°. Overall, both datasets were in good agreement and the diurnal variations were similar for all days of the cruise. The Heidelberg IO dSCDs were found to be slightly higher than those inferred from the Bremen instrument. The difference was likely due to the different choice of reference spectra selected by both groups. Since both datasets showed an overall

¹ Used the same value as CH_2ClI ;² not measured during TransBrom. The highest fluxes reported by Jones et al. (2010) are used.**Fig. 5.** Daily averaged IO dSCDs measured for elevation angles of 3° (red) along the cruise track with the dSCD detection limits displayed by blue bars (left panel). In the right panel, all inferred IO dSCDs are shown and colour-coded for different elevation angles.

good agreement, for further analysis only the Heidelberg IO dSCDs were used.

A latitudinal cross-section of inferred daily averaged IO VCDs and IO surface mixing ratios is shown in panel a of Fig. 7. In general, the retrieved IO surface mixing ratios were subject to significantly larger relative errors than the VCDs, because the measurements yielded only limited information on the shape of the IO profile, whereas the VCD was retrieved with significantly better accuracy. Largest IO VCDs and IO surface mixing ratios were present during cruise part 2 (20° N to 5° S), where the daily averaged VCD reached $3.7 \times 10^{12} \text{ molec cm}^{-2}$ and the IO mixing ratio 1.5 ppt. Panel b of Fig. 7 shows the air mixing ratios of the organic io-

dine precursor molecules CH_3I , CH_2BrI , CH_2I_2 and CH_2ClI . They indicate that the largest iodocarbon mixing ratios occurred in the southern tropical hemisphere. Furthermore, after 21 October 2009 (cruise part 3), a significant increase in CH_2ClI was observed, when the R/V *Sonne* passed Papua New Guinea and approached the north coast of Australia, where the increased biological activity was largely due to the proximity to the coast. Accordingly, biologically derived iodocarbons e.g., CH_2ClI reached mixing ratios of more than 12 ppt near the surface. Due to its short lifetime (some hours), CH_2ClI was potentially an efficient source of inorganic iodine there, but surprisingly a corresponding increase in IO was not observed. Table 5 shows an overview of the

Table 4. Overview of retrieved quantities and their errors for different IO retrieval settings, averaged over all observations from 14 October 2009. The scenario in the first column (bold) corresponds to the optimal parameters found for the spectral retrieval. The basic parameters and settings are described in Sects. 3.3 and 3.4. The dSCDs are given in units of 10^{13} molec cm^{-2} , the VCDs in units of 10^{12} molec cm^{-2} and the VMR in ppt.

Fig. 6. Comparison of IO dSCDs retrieved from 5° elevation angle observations of the Bremen (red) and the Heidelberg (blue) instruments on 14 October 2009. Since the Bremen instrument performed more elevation angles per sequences, observations at specific elevation angles are less frequent.

different parameters that were correlated with the daily averaged IO mixing ratios. Except for CH_2BrI , the daily averaged iodocarbons only indicate a weak correlation with daily averaged IO VMR ($R \leq \pm 0.25$), supporting the idea that organic iodocarbons were not the main source for reactive iodine in the MBL. Note that for CH_2BrI only three data points were available. Hence, a reliable correlation could not be obtained. Furthermore, the daily averaged oceanic Chl *a* content (Zindler et al., 2012) and the IO VMR were found to be anti-correlated with a correlation coefficient of $R = -0.70$. Thus, the oceanic Chl *a* concentrations (panel c of Fig. 7)

may not serve as a good proxy for the presence of IO in the MBL. Zeaxanthin and divinyl chlorophyll *a* are marker pigments for cyanobacteria (Zindler et al., 2012). Since both marker pigments only show a weak anti-correlation with IO VMR ($R = -0.42$, $R = -0.43$), they may also not serve as an appropriate indicator for IO.

In the latitude band between 15° N and 8° S, ozone mixing ratios measured by in-situ O_3 -sondes (Markus Rex, AWI Potsdam, personal communication) dropped to values close to zero near the surface (panel d of Fig. 7). Since the O_3 and IO mixing ratios anti-correlated with $R = -0.47$, this may lead to the conclusion that ozone was lost by iodine-mediated photochemistry or in reactions with dissolved organic matter at the ocean surface, a finding in broad agreement with recently reported results from the Eastern Pacific (Mahajan et al., 2012). At the same time reactions of ozone with dissolved organic matter (DOM) at the ocean surface could have initiated the release of iodocarbons into the atmosphere. When ozone reacts with dissolved iodide, hypoiodous acid HOI and molecular iodine (I_2) are formed at the ocean surface (e.g., Garland et al., 1980; Carpenter et al., 2013). HOI and I_2 further react with DOM to produce dissolved organic iodine (DOI). Iodocarbons can then be produced from the oxidation of iodide by ozone and the reaction of HOI with organic molecules (Garland et al., 1980; Garland and Curtis, 1981; Martino et al., 2009). However, owing to the poor correlation between the IO and ozone mixing ratio found in the data, a tighter conclusion can neither be drawn on ozone destruction by reactive iodine, nor on an ozone-driven iodine precursor production. Further, IO showed a positive correlation with relative humidity ($R = 0.60$) (panel d of Fig. 7) and with sea surface temperature (SST) ($R = 0.71$) (panel c of Fig. 7). The latter correlation might point to an increased oceanic release

Table 5. Overview of the correlation of different parameters with IO mixing ratios (daily averages).

correlation parameters	number of data points	correlation coefficient	Pearson slope of linear correlation
CH ₃ I [ppt]	7	0.25	0.150
CH ₂ ClI [ppt]	10	−0.22	−0.023
CH ₂ BrI [ppt]	3	−0.91	−5.320
CH ₂ I ₂ [ppt]	8	0.15	0.220
Chl <i>a</i> [mg m ^{−3}]	14	−0.70	−0.001
zeaxanthin [mg m ^{−3}]	14	−0.42	−0.005
divinyl chlorophyll <i>a</i> [mg m ^{−3}]	14	−0.43	−0.004
O ₃ [ppb]	12	−0.47	−0.009
humidity [%]	14	0.60	0.021
SST [°C]	14	0.71	0.076
windspeed [m s ^{−1}]	14	−0.31	−0.031

of iodocarbons due to their decreasing solubility at higher temperatures. Moreover, the Pearson correlation coefficient of wind speed and IO amounts to $R = -0.30$ (see Table 5) indicating that a correlation e.g., during the tropical storms was not observed. The relative humidity and wind speed were recorded by the weather station of the R/V *Sonne*, whereas the SST was measured by a factory calibrated temperature probe in surface seawater taken from 5 m depth in the hydrographic shaft of the R/V *Sonne*.

5 Comparison to model calculations

The measurements are compared to results obtained from the MISTRA model simulations (see Sect. 3.6). Due to the limited vertical resolution of the IO profiles retrieved from the MAX-DOAS measurements, a quantitative comparison of measured and modelled IO required the artificial degradation of the modelled profiles i.e., by applying the inferred averaging kernel according to Rodgers and Connor (2003),

$$\mathbf{x}' = \mathbf{x}_a + \mathbf{A}(\mathbf{x} - \mathbf{x}_a) \quad (1)$$

where \mathbf{x} is the modelled IO vertical profile, \mathbf{A} the MAX-DOAS averaging kernel and \mathbf{x}_a the MAX-DOAS a priori profile. The artificially degraded profile \mathbf{x}' represents the vertical profile that would have been retrieved from the MAX-DOAS measurements if the true profile would be \mathbf{x} . Since the MAX-DOAS averaging kernel varied from profile retrieval to profile retrieval, due to changes in atmospheric visibility and aerosol load, a representative averaging kernel matrix \mathbf{A} was calculated from the mean of all inferred averaging kernels (see Fig. 3).

Figure 8 shows the IO VCDs derived from the different model scenarios as listed in Table 3, together with the measured VCDs as a function of SZA and averaged for all data taken during the cruise. For all model runs the adjusted modelled VCDs were significantly larger than the unmodified

Fig. 7. Latitudinal cross-section of daily averaged IO VCDs and mixing ratios with the error bars indicating the respective daily averaged total error (a), iodocarbon mixing ratios (b), daily averaged Chl *a* concentration and sea surface temperature (SST) (c) as well as the O₃ mixing ratios averaged for the lowest 100 m from each of the different O₃-sonde profiles (upper limit of the uncertainty range in red and lower limit of the uncertainty range in black), and the daily averaged relative humidity (d).

modelled VCDs. This positive bias was caused by the choice of the a priori, which exponentially decreased with altitude and, therefore, contained some residual IO located above the model boundary layer i.e., at altitudes where the sensitivity of the MAX-DOAS measurements was very limited.

The diurnal variation of the modelled IO VCD was distinctively different for the model runs excluding (run 0) or including an additional I₂ source (run 1 and 2). In particular, the model runs including an I₂ source exhibited larger IO VCDs in the morning (maximum at ≈ 73° SZA), whereas the model run 0 (excluding an I₂ source) showed a symmetric diurnal variation. Thus, the IO peak mixing ratio in the morning resulted from the rapidly photolysed I₂ (Saiz-Lopez and Plane, 2004) that had accumulated in the MBL during the night. It was found that an additional I₂ flux of at least $j_{I_2} = 1.8 \times 10^8 \text{ molec cm}^{-2} \text{ s}^{-1}$ (run 1) was required to reproduce the measurements of cruise part 2. The artificially degraded VCDs of model run 0 excluding an additional I₂ source were $(1\text{--}1.5) \times 10^{12} \text{ molec cm}^{-2}$, which was outside the error of the measurements supporting the conclusion that an additional iodine flux is required.

In the absence of an I₂ source (run 0), the model predicted approximately twice as much IO in the MBL for part 3 as compared to part 2, mostly owing to the higher

Fig. 8. Comparison of morning (left panel) and evening (right panel) values of measured and modelled IO VCDs as a function of SZA for the cruise part 2 (upper panel) and for the cruise part 3 (lower panel). The modelled VCDs are calculated from predictions of model runs 0, 1 and 2, according to Table 3 (solid red, green and blue lines) and the corresponding artificially degraded model VCDs are indicated by dashed lines. The measured VCDs are 5° SZA averages for the cruise part 2 and 3 (black squares), respectively.

iodocarbon mixing ratios there. The additional CH₂ClI observed in cruise part 3 causes an increase in the modelled IO VCDs of about 1×10^{12} molec cm⁻² compared to cruise part 2, whereas I₂ contributes with about $(0.5\text{--}1) \times 10^{12}$ molec cm⁻². In this case the comparison of modelled and measured VCDs did not allow us to decide, if an additional I₂ source was required. However, the measurements showed elevated IO VCDs for SZAs larger than 70°, which were indicative for the presence of a short-lived inorganic iodine precursor e.g., I₂.

Panel a–d of Fig. 9 show the modelled vertical profiles of IO for run 0 and 1. Except for the early morning hours, IO was predicted to be well mixed within the boundary layer in run 0 (panel a and b of Fig. 9), mainly as a result of the relatively long photochemical lifetime of the iodocarbons (see Table 2). In contrast, for run 1 (including an I₂ source) (panel c and d of Fig. 9), IO shows a strong vertical gradient with highest IO mixing ratios near the surface. Figure 10 shows the single vertical profiles of model run 0 and 1 for cruise part 2 and 3 at noon, respectively. In model run 1 the shallow layer of enhanced IO with a strong vertical gradient near the surface is clearly visible.

Panels e–h of Fig. 9 show the same model scenarios as in panel a–d, but artificially degraded with the MAX-DOAS averaging kernel. As expected, the adjusted profiles showed much larger vertical gradients as a result of the limited vertical resolution of the MAX-DOAS measurements. However, the main features of the model run 0 and 1 were still discernable in the artificially degraded profiles. In particular, the ar-

Fig. 9. IO simulations of the MISTRA model (a–h) and inferred IO profiles from the MAX-DOAS measurements (i, j) for a typical scenario of cruise part 2 (left column) and cruise part 3 (right column). Panels (a) and (b) excluding an additional inorganic iodine flux, (c) and (d) including an additional I₂ flux of $j_{\text{part 2}} = 1.8 \times 10^8$ molec cm⁻² s⁻¹ and $j_{\text{part 3}} = 1.0 \times 10^8$ molec cm⁻² s⁻¹, respectively, (e)–(h) same as (a)–(d), but artificially degraded, (i) and (j) retrieved from the MAX-DOAS measurements for 14 October 2009 and for 23 October 2009, respectively. The colour coding represents IO mixing ratios in units of ppt.

tificially degraded profiles of run 1 showed a shallow layer of enhanced IO located directly above the surface.

Panel i of Fig. 9 shows the IO mixing ratios retrieved from the MAX-DOAS measurements during cruise part 2 on 14 October 2009, and panel j for 23 October 2009 during cruise part 3. These two days had the lowest cloud contamination of the IO profile retrieval. For both days, the measured IO profiles were similar to the prediction of model run 1, with IO being distributed over the entire depth of the boundary layer in the morning i.e., in particular seen on 23 October 2009. During the rest of this day IO was confined within a shallow layer near the surface of about 300 m in vertical extent. These findings strongly supported the hypothesis that an additional short-lived inorganic iodine compound was necessary to find a good agreement between measured and modelled IO.

Fig. 10. IO vertical profiles for different model scenarios (run 0, run 1) for cruise part 2 and 3 at 12:00 local time.

6 Conclusions

The present paper reports on a latitudinal cross-section of surface IO mixing ratios and IO profiles, which were taken in the MBL of the Western Pacific (42° N, 141° E to 19° S, 146° E). The measurements provide further evidence that IO is probably ubiquitous in the marine environment, with slightly enhanced IO being detected above warmer tropical (cruise part 2) as compared to the adjacent colder waters (cruise parts 1 and 3). The IO profiles inferred from the MAX-DOAS measurements indicate that (a) the bulk of IO with mixing ratios in the range (1–2.2) ppt was located in a shallow layer near the surface of less than 300 m in vertical extent during the day and that (b) IO is more widely distributed in the MBL in the morning.

A negative correlation of oceanic Chl *a* and atmospheric IO was observed in agreement with a recent study performed in the Eastern Pacific (Mahajan et al., 2012). Both studies are providing strong evidence that, in contrast to coastal regions where iodocarbon emissions of macroalgae are likely the major source for iodine (e.g. Seitz et al., 2010; Commancin et al., 2011), in the open ocean direct marine emissions of inorganic iodine (here assumed to be I₂) are important as a source of reactive iodine in the MBL, in line with recent findings of Carpenter et al. (2013).

This conclusion is corroborated by the following findings of our study:

1. There is no correlation between the measured IO and the organic iodine precursor species CH₃I, CH₂ClI, CH₂BrI and CH₂I₂.
2. The observed IO is underpredicted by the MISTRA model when only using iodocarbons as iodine precursors.

3. In the morning the IO peak is much smaller in the MBL, when excluding a strong inorganic iodine source, e.g., I₂, in the MISTRA model.
4. Over the course of the day IO tends to be confined to a shallow layer of enhanced IO near the surface, requiring a short-lived precursor molecule emitted from the ocean, e.g., I₂, with a flux of 1.0 to $1.8 \times 10^8 \text{ molec cm}^{-2} \text{ s}^{-1}$.

Findings 1 and 2 are in agreement with those previously reported by Jones et al. (2010) and Mahajan et al. (2010a).

Possible mechanisms for the direct oceanic emission of I₂ include (a) the reaction of ozone with dissolved organic matter at the ocean surface, as proposed by Garland and Curtis (1981) and Martino et al. (2009), (b) emission from any other abiotic source in the surface water body (Garland and Curtis, 1981; McFiggans, 2005; Carpenter et al., 2013), (c) direct emission of I₂ produced by microalgae and phytoplankton (I₂ emissions by macroalgae in coastal regions was observed at several sites, e.g., by Peters et al., 2005; Saiz-Lopez and Plane, 2004; and Finley and Saltzman, 2008), and (d) iodine liberated from the sea salt aerosol (e.g. Saiz-Lopez et al., 2012). Mechanism (c) is unlikely due to the anti-correlation between IO and Chl *a* and the lack of any correlation between IO and the organic iodine precursor species. While mechanism (d) is already implemented in the MISTRA model, our study does not give hints as to whether mechanism (a) and (b) are more relevant for our observations and for open ocean iodine emissions in general. However, there are still uncertainties regarding e.g., the heterogeneous and aqueous phase processes, and the iodine release mechanism might be underpredicted by the model (e.g., Reeser et al., 2009; Jamboul et al., 2009).

Acknowledgements. This study has been partly funded by the national WGL project TransBrom. The ship campaign on R/V *Sonne* was supported by the BMBF (German Federal Ministry of Education and Research) through grant 03G0731A. Additional funding from the project EU-SHIVA (FP7-ENV-2007-1-226224) and from the project SOPRAN (03F0462F) (funded by BMBF, the German Federal Ministry of Education and Research) is highly acknowledged. Many thanks also to Markus Rex from the Alfred Wegener Institut (AWI) Potsdam for preparing the ozone data and to Tilman Dinter from the Institut für Umweltphysik (IUP) Bremen for the VRS compensation spectrum. We further acknowledge the PHYTOOPTICS group from AWI Bremerhaven and IUP Bremen for providing the Chl *a* data.
